Crystalline Divinyldiarsene Radical Cations and Dications

Mahendra K. Sharma, Sebastian Blomeyer, Beate Neumann, Hans-Georg Stammer, Maurice van Gastel, Alexander Hinz, and Rajendra S. Ghadwal*

Dedicated to Professor Lothar Weber on the occasion of his 75th birthday

Abstract: The divinylarsenic radical cations \([((\text{NHC})C\text{(Ph)})As]_2\text{(GaCl}_3\text{)} \) \((\text{NHC} = \text{IPr}; C([\text{NDipp}]\text{CH}_2])_2\); \(\text{SiPr}; C([\text{NDipp}]\text{CH}_2)_2\); \(\text{Dipp} = 2,6\text{-iPr}_2\text{C}_6\text{H}_3\) and dications \([((\text{NHC})C\text{(Ph)})As]_2\text{(GaCl}_3\text{)} \) \((\text{NHC} = \text{IPr}; 5; \text{SiPr} 6)\) are readily accessible as crystalline solids on one-electron oxidation of the corresponding divinyldiarsenes \([((\text{NHC})C\text{(Ph)})As]_2\) \((\text{NHC} = \text{IPr}; 1; \text{SiPr} 2)\) with \(\text{GaCl}_3\). Compounds 3–6 have been characterized by X-ray diffraction, cyclic voltammetry, EPR/NMR spectroscopy, and UV/vis absorption spectroscopy as well as DFT calculations. The sequential removal of one electron from the HOMO, that is the \(\text{As}_2\text{As}\) π-bond, of 1 and 2 leads to successive elongation of the \(\text{As}_2\text{As}\) bond and contraction of the \(\text{C}_\text{As}\) bonds from 1/2 – 3/4 – 5/6. The UV/vis spectrum of 3 and 4 each exhibits a strong absorption in the visible region associated with SOMO-related transitions. The EPR spectrum of 3 and 4 each shows a broadened septet owing to coupling of the unpaired electron with two \(^{75}\text{As} \) \((I = 3/2)\) nuclei.

Stable radicals are appealing synthetic targets in main-group chemistry\([1]\) because they challenge conventional bonding paradigms as well as exhibit intriguing electronic structure and physical properties. Among the heavier Group 15 elements (P, As, Sb, Bi), numerous phosphorus-centered stable radicals\([2]\) have been isolated and structurally characterized.

However, the number of crystallographically characterized arsenic\([2a,k,p,3]\), antimony,\([4]\) and bismuth\([5]\) radicals remained limited.

In 2013, Robinson et al. reported the first stable arsenic radical cation 1 (Figure 1)\([5a]\) by one-electron oxidation of an N-heterocyclic carbene (NHC)-stabilized diatomic arsenic compound \((\text{IPr})_2\text{As}_2\)\([6]\). Grützmacher and co-workers reported the neutral radical II containing NHC-phosphini-dene substituents.\([2b,p]\) Schulz et al. isolated singlet diradicaloids III–E \((E = \text{P or As})\) featuring a 5π-electron four-membered \(\text{N}_2\text{E}_2\) ring with a considerable open-shell character.\([2g,3b]\) Consequently, III–E undergo one-electron oxidation to afford the 5π-electron radical cations IV–E.\([2g]\) Very recently, Wang and co-workers reported the radical cations \(\text{Ar}_3\text{As}^+\) \((\text{Ar} = \text{bPr}_2\text{C}_6\text{H}_3\) or \(\text{iPr}_2\text{C}_6\text{H}_3\)\).

The high-lying HOMO of III–E and \(\text{Ar}_3\text{As}\) facilitates one-electron oxidation giving rise to radical cations IV–E and V, respectively. We recently reported crystalline divinyldiarsenides 1 and 2 derived from classical NHCs, which exhibit particularly small HOMO–LUMO energy gap of 3.86 eV and 4.24 eV, respectively.\([3]\) The high-lying HOMO of 1 \((-4.42\text{ eV})\) and 2 \((-5.28\text{ eV})\) encouraged us to probe the synthetic viability of corresponding stable radical cations on one-electron oxidation of 1 and 2. Herein, we report the synthesis of crystalline divinylarsenic radical cations \([(\text{NHC})\text{C(Ph)}\text{As}]_2\text{(GaCl}_3\text{)} \) \((\text{NHC} = \text{IPr}; C([\text{NDipp}]\text{CH}_2])_2\); 3; \(\text{SiPr}; C([\text{NDipp}]\text{CH}_2)_2\); 4; \(\text{Dipp} = 2,6\text{-iPr}_2\text{C}_6\text{H}_3\) as well as dications \([(\text{NHC})\text{C(Ph)}\text{As}]_2\text{(GaCl}_3\text{)} \) \((\text{NHC} = \text{IPr}; 5; \text{SiPr} 6)\).

---

**Figure 1.** Structurally characterized arsenic-centered radicals 1–V and divinylarsenides 1 and 2.
We commenced our studies with electrochemical analyses of 1 and 2 (see Supporting Information). The cyclic voltammograms (CVs) of 1 and 2 exhibit two one-electron redox events (1: –1.00, –0.67; 2: –0.92, –0.51 V), which may be tentatively assigned to the related radical cations (1 or 2)\(^+\) and dications (1 or 2)\(^{2+}\), respectively (Supporting Information, Figure F1 and Table T5). One additional wave at –1.28 V was observed for 1 and is most likely associated with the reduction to the corresponding radical anion. However, this wave is absent in the CV of 2. Accordingly, treatment of an Et\(_2\)O solution of 1 (green) and 2 (violet) each with two equivalents of GaCl\(_3\) immediately led to the precipitation of a dark green solid. After workup, the radical cations 3 and 4 were isolated as green crystalline solids (Scheme 1). The use of an excess GaCl\(_3\) should be avoided as it leads to the over oxidized products, the dications 5 and 6. Indeed, reactions of 3 and 4 with two equivalents of GaCl\(_3\) quantitatively gave 5 and 6, respectively. Alternatively, 5 and 6 are also accessible in one-pot reaction of 1 or 2 with four equivalents of GaCl\(_3\).

Two molecules of GaCl\(_3\) are required for one-electron oxidation of 1 and 2. The putative oxidizing species is (GaCl\(_3\))\(^+\) that is formed according to 2GaCl\(_3\)+–(GaCl\(_3\))\(^+\) + (GaCl\(_3\))\(^+\). The reduction of (GaCl\(_3\))\(^+\) yields GaCl\(_2\), which eventually disproportionates to form the stable mixed-valence Ga\(^{4+}\)/Ga\(^{3+}\) compound [Ga(GaCl\(_4\))] (Supporting Information). Compounds 3-6 are stable under an inert gas atmosphere but readily decompose when exposed to air. Compounds 3 and 4 were NMR-silent, thus indicating their paramagnetic nature. The dications 5 and 6 are red crystalline solids and exhibit well-resolved \(^1\)H and \(^31\)P/\(^1\)H NMR signals for the N-heterocyclic vinyl (NHV) moieties (Supporting Information).

Solid-state molecular structures of 3 (Figure 2), 4 (Figure 3), 5 (Figure 4), and 6 (Supporting Information, Figure F8) were determined by X-ray diffraction, which exhibit the intact As–As bond with trans-bent geometries along the two-coordinated arsenic atoms. The HOMO of diarsenes 1 and 2 is the \(\pi\)-orbital of the As=As bond.\(^{[8]}\) Thus, the formation of 3 and 4 as well as 5 and 6 is the result of sequential one electron removal from the HOMO of 1 and 2. Clearly, this leads to a steady increase in the As–As bond length of 3 (2.322(1) Å) and 5 (2.419(1) Å) as well as 4 (2.330(1) Å) and 6 (2.414(1) Å) with respect to those of 1 (2.290(1) Å) and 2 (2.290(1) Å) (Table 1). The C2–As1/C4–As2 bond lengths of 3 (1.867(4) Å) and 4 (av. 1.876(2) Å) are shorter compared to that of 1 (1.919(1) Å) and 2 (1.936(3) Å) respectively. The C1–C2/C3–C4 bond lengths of 3 (1.424–(3) Å) and 4 (av. 1.420(2) Å) are however rather stretched with respect to those of 1 (1.376(2) Å) and 2 (1.369(3) Å).
Moreover, the C2 (1.54), and the EPR spectra were reported (Figure 1). Based on TD-DFT calculations, the band at 822 nm (1.21) may be assigned to the SOMO orbital at C4 of the corresponding radical cation (Supporting Information, Figure F3) and (89.0(1) eV) for both (α, β) spin states. Hydrogen atoms as well as isopropyl groups are omitted for clarity.

This can be rationalized as the increase of the formal positive charge on the arsenic atoms of 3 and 4 leads to the π-electron density transfer from the vinyllic C=C bond to the arsenic atom. As expected, a more pronounced trend in the elongation of As1-As1’/As2 and C1–C2/C3–C4 bonds while the contraction of the C2–As1/C4–As2 bond lengths of dications 5 and 6 is observed compared to radical cations 3 and 4. The As–As bond length of 5 (2.414(4) Å) and 6 (2.414(4) Å) is longer than that of radical cations 3 (2.322(5) Å) and 4 (2.330(3) Å), however it is still shorter compared to an As–As single bond (ca. 2.46 Å).[10] Moreover, the C2–As1/C4–As2 bond lengths of 5 (1.836(3) Å) and 6 (av. 1.830(3) Å) are longer than the C=As double bond length of arsalkenes (1.75–1.79 Å).[11] The As–As bond lengths of dications (95.7(9)°) is comparable with that of the corresponding radical cations (99.7(1)°) as well as for the C2/C4 and C3/C4 units. The computed NPA atomic partial charges (Supporting Information, Table T4) indicate that the density transfer from the vinylic C=C bond to the arsenic atom.

Further insights into the electronic structures of 3–6 were obtained by DFT calculations. The optimized bond lengths of 3–6 at the M06-2X/def2-TZVP/M06-2X/def2-SVP level of theory (Supporting Information) show good agreement with their solid-state structures. The computed NPA atomic partial charges (Supporting Information, Table T4) indicate that the As, fragment in 3 (+0.40e), 4 (+0.47e), 5 (+0.57e), and 6 (0.62e) carries a positive charge, which is higher than that in 1 (+0.27e) and 2 (+0.32e).[12] Each of the vinyl (C2/C4) carbon atoms of 3 (-0.54e), 4 (-0.56e), 5 (-0.47e), and 6 (-0.56e) bears a negative, whereas the carbenc carbon (C1/ C3) of 3 (+0.42e), 4 (+0.52e), 5 (+0.41e), and 6 (+0.55e) bears a positive charge. The WBLs (Wieberg bond indices) for the As–As bond of 3 (1.25), 4 (1.24), 5 (1.00), and 6 (0.99) as well as for the C2/C4–As bonds of 3 (1.21), 4 (1.19), 5 (1.54), and 6 (1.53) indicate the delocalization of π electrons over the C2AsC2 π-electron system.

Table 1: Selected bond lengths [Å] and angles [°] of diarsenes (1, 2) and the corresponding radical cations (3, 4) and dications (5, 6).

[a] As1–As1’ / As2. [b] Molecular structure features crystallographic center of inversion (C3).

Figure 5. Molecular orbitals (isovalue 0.04) of the radical cation 3 calculated at M06-2X/def2-TZVPP//def2-SVP level of theory with energies (eV) for both (α, β) spin states. Hydrogen atoms as well as isopropyl groups are omitted for clarity.

Figure 6. X-Band EPR spectra of 3 and 4 at 80 K in THF (ν=9.63 GHz, Mod. Amp. 5G, P mw = 2 mW).

The EPR spectra of 3 and 4 were recorded in THF at 9.63 GHz. At 298 K, 3 and 4 exhibit a featureless singlet (Supporting Information, Figures F6 and F7) while at 80 K a broadened septet with poorly resolved hyperfine components was observed because of coupling with two magnetically equivalent 75As nuclei (Figure 6). These features are similar to those of the radical cation 1 (Figure 1) reported earlier by Robinson and co-workers.[13] The EPR spectra were simulated by using the g values, the hyperfine couplings of each As and ortho hydrogen atoms of the phenyl groups, and three linewidth parameters to take into account unresolved hyperfine couplings (Supporting Information, Table T11).
The calculated Mulliken atomic spin density for 3 and 4 (Figure 7) reveals that the unpaired electron is mainly located at the π-conjugated CAs, C framework (Supporting Information, Table T10). In 3, 12% of spin-density is located at each of the arsenic atoms whereas the spin density at each of the vinylic carbon atoms is 20%. The spin density at each of the ring nitrogen atoms of 3 and 4 is 5%. Remarkably, the spin density at the original carbene carbon atom is negligible. In comparison with 3, the spin density at the arsenic atoms (16% each) of 4 is higher compared to that of 3 (12% each). Furthermore, the spin density at the vinylic carbon atoms (15% each) of 4 is lower with respect to that of 3 (20% each). This is most likely due to the puckered (non-planar) structure of 1,3-imidazoline rings of 4 that twist the vinylic C=C bond out of the AsAs bond plane, leading to a diminished π-conjugation compared to that in 3 featuring planar 1,3-imidazole rings. This is also revealed in the X-ray structures of 3 and 4 (Figures 2 and 3). The C3N2 ring plane angle of 3 (6.53(14)°) is considerably smaller compared with that of 4 (83.33(11)°). Similarly, the C2-As1-As2-C4 torsion angle of 178.57(14)° in 3 is larger than that in 4 (163.37(8)°).
